Introduction and objectives:

Preterm infants often present CH characterized by delayed TSH elevation. We describe the clinical and biochemical features and the evolution of CH in preterm infants with delayed TSH elevation, detected by the 2nd screening for CH.

Methods:

All preterm infants born in Lombardy Region between 2007-2014 negative to the 1st screening (b-TSH<10 mcU/ml) at 2-5 days of life and positive to the 2nd screening at 12-33 days (b-TSH ≥5 mcU/L), diagnosed with CH and followed-up in a single tertiary Centre of paediatric endocrinology were included (figure 1).

According to the result of the thyroid function testing after the withdrawal of therapy, at 2-3 years, patients were divided into 3 groups, as shown in figure 2.

Results:

46 preterm patients were included in the study (26 males). At diagnosis, the neck ultrasound showed 1 ectopy, 1 hemiagenesis, and 44 cases of GIS. Treatment was started at a median age of 40 days (15-89).

Two patients had thyroid dysgenesis. Among the 44 patients with GIS, 37 were reevaluated. At reevaluation:

• 4 patients had permanent CH (s-TSH 17,9-24,1 mcU/ml), requiring the reintroduction of LT4
• 10 had persistent hyperthyrotropinemia
• 23 had transient CH

The 4 permanent cases with GIS were moderate-to-late preterm (32-36 GW), 2/4 were twins and in both cases the other twin (not included in the study) had hyperthyrotropinemia. Moreover, they showed only mild s-TSH elevation at diagnosis (s-TSH 14,40-19,77 mcU/ml).

Conclusions:

• We confirmed the usefulness of the second-screening strategy for CH to detect preterm infants who otherwise would not be identified at the first screening.
• Although preterm infants very often have transient CH, many of them may have severe CH at diagnosis, which requires prompt treatment, and some others may have permanent CH (including thyroid dysgenesis), despite mild TSH elevation at diagnosis.
